Abstract—The wide adoption of third-party libraries in software projects is beneficial but also risky. An already-adopted third-party library may be abandoned by its maintainers, may have license incompatibilities, or may no longer align with current project requirements. Under such circumstances, developers need to migrate the library to another library with similar functionality, but the migration decisions are often opinion-based and sub-optimal with limited information at hand. Therefore, several filtering-based approaches have been proposed to mine library migrations from existing software data to leverage “the wisdom of crowd,” but they suffer from either low precision or low recall with different thresholds, which limits their usefulness in supporting migration decisions.

In this paper, we present a novel approach that utilizes multiple metrics to rank and therefore recommend library migrations. Given a library to migrate, our approach first generates candidate target libraries from a large corpus of software repositories, and then ranks them by combining the following four metrics to capture different dimensions of evidence from development histories: Rule Support, Message Support, Distance Support, and API Support. We evaluate the performance of our approach with 773 migration rules (190 source libraries) that we borrow from previous work, and we confirm 661 new migration rules included in prior work, and we verify the recommendation results of 480 popular libraries not included in prior work, and we confirm 661 new migration rules from 231 of the 480 libraries with comparable performance. The experiments show that our metrics are effective to help identify real migration targets, and our approach significantly outperforms existing works, with MRR of 0.8566, top-1 precision of 0.7947, top-10 NDCG of 0.7702, and top-20 recall of 0.8939. To demonstrate the generality of our approach, we manually verify the recommendation results of 480 popular libraries not included in prior work, and we confirm 661 new migration rules from 231 of the 480 libraries with comparable performance. The source code, data, and supplementary materials are provided at: https://github.com/hehao98/MigrationHelper.

Index Terms—library migration, mining software repositories, library recommendation, multi-metric ranking

I. INTRODUCTION

Modern software systems rely heavily on third-party libraries for rich and ready-to-use features, reduction of development cost and productivity promotion [1], [2]. In recent years, the rise of open-source software and the emergence of package hosting platforms, such as GitHub [3], Maven Central [4] and NPM [5], has led to an exponential growth of open source libraries. For example, the number of newly-published JARs in Maven Central is 86,191 in 2010, 364,268 in 2015, and over 1.2 million in 2019 [4]. Nowadays, open-source libraries can satisfy a diverse spectrum of development requirements, and are widely adopted in both commercial and open-source software projects [6].

However, third-party libraries are known to cause problems during software evolution. First, third-party libraries may have sustainability failures [7], [8]. They may be abandoned by their maintainers due to lack of time and interest, difficulty in maintenance, or being superseded by competitors [7]. Second, third-party libraries may have license restrictions [9], [10]. If a project uses a GPL-licensed library during early prototyping, it must be replaced before the project is released as proprietary software. Finally, third-party libraries may fail to satisfy new requirements due to absence of features, performance issues, etc. Suppose a Java application at its infancy stage is using org.json:json [11] for its simplicity. When the application matures and scales, it often has to migrate to another JSON library for richer features or higher performance (see Figure 1 for an example). To address any of these issues, software projects have to replace some already-used libraries (i.e., source libraries) with some other similar or functionality-equivalent libraries (i.e., target libraries). Such activities are called as library migration in the related literature [12]–[19].

However, it is often not easy to find good target libraries and choose between a number of candidate libraries [12], [20], [21]. Community curated lists such as awesome-java [22] and AlternativeTo [23] are often non-informative and contain low quality libraries, while blog posts and articles tend to be opinion based and outdated [20]. The easily accessible metrics such as popularity and release frequency have limited usefulness and they vary with domain [21]. In practice, industry projects often rely on domain experts for making

Fig. 1. An example migration between JSON libraries
mining and ranking library migration

ACKGROUND and recall and top-problem, ranking to refer to the Normalized Discounted changes. Given a source library, our approach first because we observe that relative ranking positions are not only candidate rules along with their metrics. The candidate rules libraries as query to our approach, which returns 243,152 collected 21,358 repositories and get a ground truth of 773 we recover and extend migration rules in [14] from the Maven artifact. To evaluate the performance of our approach, libraries.io [25], and extract API information for each collected configuration files. To support metric computation, we also of 21,358 Java GitHub repositories and successfully extract migration suggestions or support their migration decisions. To support metric computation, the underlying rationale is that functional migrations, as in [12]–[19].

To improve the effectiveness of these approaches [12], [14], [17], we propose a new approach for automated recommendation of library migration targets from existing software development histories. Instead of mining and filtering, we formulate this problem as a mining and ranking problem, because we observe that relative ranking positions are not only more important but also more robust to metric and parameter changes. Given a source library, our approach first mines target library candidates from the dependency change sequences (defined in Section II-B) built from a large corpus of software development histories. After that, the candidates are ranked based on a combination of four carefully designed metrics: Rule Support, Message Support, Distance Support and API Support. The metrics are designed to capture different sources of evidence from data and pinpoint likely migration targets based on the evidences. Finally, the top target libraries, their metrics, and the relevant migration instances are returned for human inspection. Our approach is implemented as a web service, which can be used by project maintainers to seek migration suggestions or support their migration decisions.

To implement our approach, we collect version control data of 21,358 Java GitHub repositories and successfully extract 147,220 dependency change sequences from their dependency configuration files. To support metric computation, we also collect Maven artifacts from Maven Central [4] using Libraries.io [25], and extract API information for each collected Maven artifact. To evaluate the performance of our approach, we recover and extend migration rules in [14] from the collected 21,358 repositories and get a ground truth of 773 migration rules (190 source libraries). We use the 190 source libraries as query to our approach, which returns 243,152 candidate rules along with their metrics. The candidate rules include all ground truth migration rules mentioned above. Then, we estimate and compare survival functions for each metric, and compute Mean Reciprocal Rank (MRR) [26], top-k precision, top-k recall and top-k Normalized Discounted Cumulative Gain (NDCG) [27] for our approach along with existing approaches and a number of other baselines. Finally, we experiment our approach on additional 480 popular libraries both to ensure our approach is generalizable and to confirm more real world migrations. Our experimental evaluations show that the metrics are effective to help identify real migration targets from other libraries, the method that combines all four metrics can reach MRR of 0.8566, top-1 precision of 0.7947, top-10 NDCG of 0.7702 and top-20 recall of 0.8939 in the ground truth dataset, and we confirm 661 new migration rules with comparable performance. Our approach has been deployed in a proprietary 3rd-party library management tool to recommend migration targets for libraries in the deny list.

We make the following contributions in this study:

1) formulate the library migration recommendation problem as a mining and ranking problem,
2) propose a new multi-metric ranking approach via mining dependency change sequences, which significantly outperforms existing approaches,
3) implement and conduct a systematic evaluation for our approach, showing that the approach is effective in suggesting migration targets for Java Maven projects,
4) provide a latest ground truth dataset of 1,384 migration rules and 3,340 related commits discovered from 1,651 open source Java projects. The dataset can be used to facilitate further research in library migration.

II. BACKGROUND

We first provide a brief introduction to the context of our approach. We then define common terminologies and a dependency model, and formulate the library migration recommendation problem. Finally, we discuss the existing approaches provided by Teyton et al. [12], [14] and Alrubaye et al. [17], before introducing our approach in the next section.

A. Library Migration

Migration is a common phenomenon in software maintenance and evolution, and may refer to different development activities that stem from various motivations. Common cases of migrations in software development include: migrating from a legacy platform to a modern platform [28], [29], one programming language to another programming language [30]–[36], one library version to another library version [37], [38], one API to another API [13], [16], [39]–[44], or one library to another library [12], [14], [15], [17], [45], [46]. In this paper, we use the term library migration to refer to the process of replacing one library with another library of similar functionalities, as in [12]–[19].

Two steps are typically needed for a library migration. The first step is to decide which library to migrate to and whether a migration is worthy. The second step is to conduct
the real migration by modifying API calls in source code, changing configuration files, etc. For example, Kabimina et al. [15] study logging library migrations in Apache Software Foundation (ASF) projects. They discover that ASF projects conduct logging library migrations for flexibility, new features and better performance, but the code changes are hard and bug-prone, and some projects fail to migrate due to absence of submitted patches or lack of maintainers’ consensus. Given current situation, the main objective of our approach is to provide explainable and evidence based support to the first step of migration, such that developers can make the most appropriate migration decision for their project based on the recommendation results. As introduced earlier, the existing approaches to achieve this goal suffer from low precision or low recall, and limited usefulness in practice.

B. Terminologies and Dependency Model

Let \( \mathcal{P} \) be the set of projects and \( \mathcal{L} \) be the set of libraries to be analyzed. A project \( p \in \mathcal{P} \) has a set of revisions \( \text{Rev}(p) = \{r_1, r_2, \ldots, r_n\} \), where each revision has zero, one or more parent revisions. We define \( r_i < r_j \) if \( r_i \) happens before \( r_j \) in \( p \), and vice versa. For each revision \( r_i \in \text{Rev}(p) \), it depends on a set of libraries \( L_i \subseteq \mathcal{L} \), which we call dependencies of \( r_i \). By comparing with its parent revision(s) (e.g. \( r_{i-1} \)), we can extract the dependency changes of \( r_i \) as

\[
L_i^+ = L_i - L_{i-1} \tag{1}
\]

\[
L_i^- = L_{i-1} - L_i \tag{2}
\]

where \( L_i^+ \) is the set of added libraries and \( L_i^- \) is the set of removed libraries. By sorting all revisions in topological order and aggregating dependency changes, we can build a dependency change sequence \( D_p \) for project \( p \).

\[
D_p = L_1^+, L_2^+, L_3^+, \ldots, L_n^+, L_n^-, L_{n-1}^-, \ldots, L_2^-, L_1^- \tag{3}
\]

We use the term \textit{dep seq} as an abbreviation of dependency change sequence in the subsequent paper.

For library \( a \in \mathcal{L} \) and library \( b \in \mathcal{L} \), we consider \((a, b)\) as a migration rule if and only if \( \exists p \in \mathcal{P}, r_i, r_j \in \text{Rev}(p), p \) has conducted a migration from \( a \) to \( b \) between \( r_i \) and \( r_j \), where \( b \in L_i^+ \) and \( a \in L_j^- \). Note that a migration may either happen in one revision \( (r_j = r_i) \), or spans over multiple revisions \((r_i < r_j)\). We refer to \( a \) as \textit{source library} and \( b \) as \textit{target library} in the subsequent paper.

Figure 2 shows an artificial example of a dependency change sequence where a project performs a migration from library \( A \) to \( F \) in revision \( r_5 \). In this case, \( L_5^- = \{ F \} \) and \( L_5^+ = \{ A \} \), and \((A, F)\) is a migration rule by our definition.

1See Section VIII for related work about the second step.
2We will discuss how we deal with multi-parent revisions in Section IV.

C. Problem Formulation

We formulate the problem of library migration recommendation as follows. Let \( \mathcal{R} \) be the set of all migration rules. Given projects \( \mathcal{P} \), libraries \( \mathcal{L} \), dep seqs \( D_p \) for \( p \in \mathcal{P} \), and a set of library queries (i.e. source libraries) \( \mathcal{Q} \), the objective of \textit{library migration recommendation} is to identify migration rules with both high coverage (for objectivity) and accurate results (for minimizing human inspection effort). For library \( a \in \mathcal{Q} \), an approach should seek to find \textit{migration targets}

\[
T = \{(a, b) \in \mathcal{R}\}
\]

We view this problem as a two-step mining and ranking problem. In the mining step, an approach should generate a \textit{candidate rule} set \( R_c \) from all dep seqs. In the ranking step, for all \( (a, b) \in R_c \), it should compute a confidence value \( \text{conf}(a, b) \) and sort \( R_c \) by this value. It should ensure that the target libraries in top ranked candidate rules are more likely to be real migration targets.

D. Existing Approaches

In this section, we introduce several existing approaches under our problem formulation. Teyton et al. [12] define candidate rules as the Cartesian product of added and removed libraries in the same revision. More formally, for project \( p \),

\[
R_{p}^c = \{(a, b) | (a, b) \in L_j^- \times L_i^+, r_i \in \text{Rev}(p)\} \tag{4}
\]

And they define confidence value as the number of revisions a rule occurs divided the maximum number of all rules with same source or same target as follows.

\[
\text{conf}_T(a, b) = \frac{|\{r_i | (a, b) \in R_{p}^c\}|}{\max(|\{(a, x) \in R_c^p | \}, |\{(x, b) \in R_c^p\}|)} \tag{5}
\]

It captures most frequent rules and is partially reused in our first metric \( RS \) (Section III-B1). Their approach requires manual specification of a threshold \( t \), and they consider a candidate rule \((a, b)\) as a migration rule if and only if \( \text{conf}(a, b) \geq t \). In their evaluation, by setting \( t = 0.06 \), they confirm 80 migration rules with a precision of 0.679 in 38,588 repositories.

In their subsequent work [14], they also consider migrations that spans over multiple revisions, using the following definition of candidate rules

\[
R_{c} = \{((a, b) | (a, b) \in L_j^- \times L_i^+, r_i \leq r_j\} \tag{6}
\]

By this definition, \((A, C), (A, D), (A, E)\) and \((A, F)\) in Figure 2 will all be considered as candidate rules given \( A \) as source library. In the hope of covering as many migration rules as possible, they manually verify 17,113 candidate rules generated from 15,168 repositories, in which they successfully confirm 329 migration rules.

Alrubaye et al. [17] propose a tool called MigrationMiner, which uses the same candidate rule definition as in [12], but filters candidate rules by their relative frequency and whether API replacements occur in code changes. Their filtering strategy can be effectively described in our framework as Rule Support \( RS \) and API Count \( AC \).

We will discuss how we deal with multi-parent revisions in Section IV.
100% precision. Table I provides a summary and comparison of existing approaches along with ours.

### III. OUR APPROACH

Our approach for recommending library migration involves two steps, a mining step and a ranking step. We first describe how candidate rules are mined for each dep seq. Then we detail how we design the four ranking metrics. Finally, we describe the confidence value, ranking strategy, and the pseudo code for our final algorithm.

#### A. Mining Candidate Rules

Given a library \( a \), the first step of our recommendation algorithm is to find a set of candidate rules \( \{ (a, x) \} \), in which \( x \) may be a feasible migration target. We follow a similar process like in [14] for mining candidate rules \( R_c \) (Equation 7), due to its high coverage. Since it is known to generate many false positives, we will specifically consider candidate rules mined from the same revision \( R_{c,i} \) in Equation 4 during metric computation. We also collect all the relevant revision pairs for each candidate rule \( (a, b) \), defined as

\[
\text{Rev}(a, b) = \{ (r_i, r_j) \mid a \in L^+_j \land b \in L^+_i \land r_i \leq r_j \} \tag{8}
\]

#### B. Four Metrics for Ranking

1) **Rule Support:** For each candidate rule \((a, b)\), we define Rule Count \( RC(a, b) \) as the number of times \( a \) is removed and \( b \) is added in the same revision:

\[
RC(a, b) = | \{ r_i \mid (a, b) \in R_{c,i}, \forall p \in P, r_i \in \text{Rev}(p) \} | \tag{9}
\]

We define Rule Support \( RS(a, b) \) as Rule Count divides the maximum value of Rule Count for all candidate rules with \( a \) as source library:

\[
RS(a, b) = \frac{RC(a, b)}{\max_{(a, x) \in R_c} RC(a, x)} \tag{10}
\]

This metric is basically a reuse of \( conf_T(a, b) \) in Equation 6, based on the intuition that the most frequent same-revision dependency changes are more likely to be library migrations. We omit the second denominator because it can only be computed with a full-scale mining \((Q = L)\), which is costly given the current number of libraries.

2) **Message Support:** Besides the “implicit” frequency-based hint characterized by Rule Support, we observe that the “explicit knowledge” provided by developer written messages accompanying revisions (e.g. commit messages or release notes) is extremely valuable. Therefore, we design the following heuristic to determine whether a revision pair \((r_i, r_j)\) seems to be doing a migration from \( a \) to \( b \):

1) First, we split the names of \( a \) and \( b \) into possibly informative parts, because developers often use shortened names to mention libraries in these messages.
2) For \( r_i = r_j \), we check whether its message is stating a migration from \( a \) to \( b \).
3) For \( r_i \neq r_j \), we check whether the message of \( r_i \) is stating the introduction of library \( b \) while mentioning \( a \), and whether the message of \( r_j \) is stating the removal of \( a \) as a cleanup.

The checks are implemented via keyword matching of library name parts along with different hint verbs for migrations, additions, removals, and cleanups. For example, we consider words like “migrate”, “replace”, “switch” as hinting a migration. We also iteratively refined the keyword matching strategies using ground truth commits discovered in Section V.

Let \( h(r_i, r_j) \mapsto \{0, 1\} \) be the heuristic function described above, where \( h(r_i, r_j) = 1 \) when the messages are considered as indicating a migration by our heuristic. We define Message Count \( MC(a, b) \) as the number of revision pairs \((r_i, r_j)\) whose messages are indicating a migration from \( a \) to \( b \), where \( b \) is added in \( r_i \) and \( a \) is removed in \( r_j \):

\[
MC(a, b) = | \{(r_i, r_j) \mid (r_i, r_j) \in \text{Rev}(a, b) \land h(r_i, r_j) \} | \tag{11}
\]

And we further define Message Support \( MS(a, b) \) as:

\[
MS(a, b) = \log_2(MC(a, b) + 1) \tag{12}
\]

3) **Distance Support:** The previous two metrics do not take into consideration multi-revision migrations without any meaningful messages, but such cases may still be common because not all developers write high quality messages. Based on the observation that most real target libraries are introduced near the removal of source library, we design the Distance Support metric to penalize the candidates that often occur far away. Let \( dis(r_i, r_j) \) be the number of revisions between revision \( r_i \) and \( r_j \) (0 if \( r_i = r_j \)). We define Distance Support \( DS(a, b) \) as the average of the inverse square distances of all revision pairs \((r_i, r_j)\) in \( \text{Rev}(a, b) \):

\[
DS(a, b) = \frac{1}{|\text{Rev}(a, b)|} \sum_{(r_i, r_j) \in \text{Rev}(a, b)} \frac{1}{(dis(r_i, r_j) + 1)^2} \tag{13}
\]

4) **API Support:** Another strong information source of a library migration is the real code modifications and API replacements performed between the two libraries. To capture this, we define API Count \( AC(a, b) \) as the number of code hunks\(^3\) in \( \text{Rev}(a, b) \) where the APIs (i.e. references to public

\(^3\)A hunk is a group of added and removed lines extracted by the diff algorithm of a version control system.

methods and fields) of $b$ are added and the APIs of $a$ are removed. Then, we define API Support as

$$AS(a, b) = \max(0.1, \frac{AC(a, b)}{\max(a, x) \in R_c AC(a, x)})$$

(14)

The reason for setting a minimum threshold is to make $AS$ more robust in case no API change is detected for some migration rules. It happens either because the code changes are not performed synchronously with dependency configuration files, or because some libraries can work solely with configuration files. For example, a manual analysis of 100 migration commits from ground truth (Section V-B) reveals that 45 migration commits do not contain any relevant API changes, in which 26 commits only modify pom.xml files, 12 commits modify configuration files, and others modify code in a way that the library APIs are not co-changed in one hunk.

C. Recommending Migration Targets

Our recommendation algorithm combines the four metrics introduced above to generate a final confidence value for all candidate rules, using a simple multiplication as follows:

$$conf(a, b) = RS(a, b) \cdot MS(a, b) \cdot DS(a, b) \cdot AS(a, b)$$

(15)

For each library query $l \in Q$, the corresponding candidate rules are sorted by this confidence value from the largest to smallest. If the confidence values of some candidate rules are the same, we further sort them using $RS$. Finally, the recommendation results along with the relevant revision pairs, grouped by each library query, are returned for human inspection. Algorithm 1 provides a full description of our migration recommendation algorithm. After initialization of the required data structure (line 1-5), we generate the candidate rules and accumulate necessary data for metric computation in one iteration of all projects and their dep seqs (line 6-14). After that, the metrics and confidence values are computed through another iteration of all candidate rules (line 15-24).

Several important optimizations can be applied to Algorithm 1. First, the initialization in line 2-4 can be done lazily to avoid excessive memory consumption. Second, for a project with length $n$ dep seq, the iteration in line 6 can be efficiently done in $O(n)$ by reversely traversing through the dep seq while maintaining a set of removed libraries and relevant revisions. Finally, we can precompute $AC(a, b)$ for all $(a, b) \in L \times L$ through one iteration of all project diffs, to avoid costly and often repetitive on-demand computation of $AC(a, b)$.

trivial by parsing the pom.xml files. Each pom.xml file has a dependency section where developers can declare used libraries by stating their library group IDs, artifact IDs and version numbers. During compilation, most declared libraries are downloaded from Maven Central [4], which provides a central hosting service for most Java open source libraries indexed as “artifacts.” We consider artifacts with the same group ID and artifact ID as one library, and the version string as marking the different versions of a library. We do not consider version number during recommendation. Although multiple (group ID, artifact ID) may refer to the same library, we do not handle such aliases, because we observe that a renaming of group ID and artifact ID often accompanies important library changes, such as major version updates, intentional dependency shadowing, etc. Therefore, we consider the migrations between such aliases as ineligible migration rules. However, we do not consider target libraries with the same group ID as source library, because we observe that they are often siblings, sub-components or auxiliary libraries that are very unlikely to be a real migration target.

B. Implementation Environment

We implement our approach on a Red Hat Linux server with 2 Intel Xeon E5-2630 v2 CPUs, 400GB RAM and 20TB storage. It has access to World of Code [48], a database for storing open source version control data including almost all repositories from GitHub. We use World of Code because
it offers much higher performance when constructing dep seqs, compared with directly cloning from GitHub and analyzing with `git`. The data is constructed using a collection of Java programs and Python scripts, and stored in a local MongoDB [49] instance. The final recommendation service is implemented in Java using the Spring framework [50].

C. Data Collection

1) Library Metadata and API Retrieval: We use the Libraries.io dataset [25] (last updated in January 2020) to get a list of Maven artifacts and their metadata. After updating the latest version information from Maven Central in October 2020, we get a total of 184,817 distinct libraries for mining candidate rules, and 4,045,748 distinct library versions for API extraction. Then, we download the corresponding JAR file from Maven Central for each version, if it has one. The total size of downloaded JAR files is approximately 3TB, but they can be safely deleted after the APIs are extracted. For each JAR file, we use Apache Commons BCEL™ library [51] to extract all public classes along with their fields and methods and store each class as a document in MongoDB. Each document describes a unique and compact class signature object describing its fields, methods, inheritance relationships, etc. They are indexed by SHA1 computed from all its properties. We also maintain mappings between library versions and classes. Finally, we get 25,272,024 distinct classes in total. The whole download and extraction process takes about 3 days to finish with 16 parallel threads on our server.

2) Dep Seq Construction: We use the GitHub repository list provided by the Libraries.io dataset, in which we select non-for fork repositories with at least 10 stars and one `pom.xml` file, resulting in 21,358 repositories. We set the 10-stars threshold to ensure that the collected repositories are of sufficient quality. The repository commits and blobs are then retrieved and analyzed from World of Code version R (last updated April 2020). A repository may have multiple `pom.xml` files in different paths for different sub-projects or sub-modules, so we consider each file as tracking the dependency of one project, and choose to construct one dep seq for each of the `pom.xml` files. For each `pom.xml` file, we extract all commits where this file is modified, separately parse its old version and new version to see whether any library is added or removed. For merge commits, we only compare with one of its old version due to design and performance constraints. For parallel branches, we sort changes by time and merge them into one dep seq. We then clean duplicate changes introduced by merge commits or parallel branches. After filtering out dep seqs with only one revision, we finally get 147,220 different dep seqs.

3) API Count Precomputation: As mentioned in Section III-C, it is worthwhile to precompute an API Count table for each \((a, b) \in L \times L\), because on-demand computation during recommendation is not only time-consuming but also inefficient in that many Java file diffs will be analyzed multiple times for different candidate rules. Therefore, we iterate over all Java file diffs for each repository, while maintaining a set of current candidate rules, to see whether some of them should increment their API Count values. The whole computation can be done in a highly parallel manner both for each repository and for code analysis of different Java file pairs. In the end, we get 4,934,677 library pairs with non-zero AC values. The whole computation takes about two weeks to finish with 16 threads, but we believe it can be further optimized and only needs to be run once, because the table can be incrementally updated when new repository data come in. Table II provides an overview of the final recommendation database we use.

V. EVALUATION

In this section, we first introduce two research questions for evaluation. Then, we describe how we build two ground truth datasets for different evaluation purposes. At last we show the evaluation methods and results for each research question.
A. Research Questions

Our main goal is to evaluate the effectiveness of Algorithm 1 in recommending library migration targets. Since the algorithm mainly relies on a confidence value computed from four metrics (Equation 15), we first verify the effectiveness of each proposed metric, forming the first research question:

- **RQ1**: How effective is $RS$, $MS$, $DS$, and $AS$ in identifying real migration targets?

Then, to show that our approach has good overall performance, we ask the second research question:

- **RQ2**: What is the performance of our approach, compared with baselines and existing approaches?

B. Ground Truth

We use two ground truth datasets for different evaluation purposes. The first is borrowed from previous work [14] and recovered in the 21,358 repositories we collect. This set of ground truth has reasonably good coverage for the source libraries in it, so we can compute accurate performance metrics and compare different approaches. The second is manually verified from the recommendation results of our algorithm on the 21,358 repositories, with 480 most popular libraries as queries. We use this dataset to verify that our approach can generalize well on a new dataset and confirm real word migrations with comparable performance. In the subsequent section, we refer to the first ground truth set as GT2014 and the second as GT2020.

1) **GT2014**: We choose to recover a new ground truth of migration rules based on the ground truth in [14], as the current situation may have significantly changed since its publication. The ground truth in [14] consists of 329 “abbreviated” library name pairs which may correspond to multiple group IDs and artifact IDs. They solve the aforementioned library aliasing issue (Section IV-A) through manual abbreviation, but we consider it too costly to repeat this on the 180k libraries we collected. As the Maven artifact pairs before abbreviation is not provided in [14], we choose to map the rules back to group IDs and artifact IDs. To cover as much migration rules as possible, we consider all pairs in Cartesian product as possible rules for multiple mappings. We also conduct reverse and transitive expansion of the rules until saturation (i.e. $(a, b) \in R \Rightarrow (b, a) \in R$, $(a, b) \in R \land (b, c) \in R \Rightarrow (a, c) \in R$), based on the intuition that libraries within one functionality category can be replaced with any other library in the same category. We get 3,878 “possible” migration rules after extension.

Recall in Section II-B that we define a migration rule as a rule that we can confirm at least one migration in one project, so the rules collected before may still contain many false positives by this definition. Therefore, we collect all relevant commits for these rules, filter them by commit messages, and manually label the rules using the following criteria:

1) If library $a$ and library $b$ provide obviously different functionalities, we label $(a, b)$ as false.
2) For other rules, we manually check the “most possible” commits by applying the message matching algorithm in Section III-B2. If there exist some messages stating a migration from $a$ to $b$, we label $(a, b)$ as true.
3) Otherwise, we check the commit diffs for easily understood small commits, and only label $(a, b)$ as true when we can find at least one understandable commit performing a migration from $a$ to $b$.

The labelling process is done by three of the authors with at least one year of Java development experiences. They are asked to search any unfamiliar libraries on Google, read through relevant websites, and consult Java veterans in our social network, until they become familiar with the libraries. To mitigate threats brought by manual labelling, we adopt a conservative labelling strategy and ensure all rules with true labels are double checked by the author with 3 years of Java experiences and 1 year of industry experiences. We also manually check the top-20 recommendation results and add any new migration rules using the same labelling process.

Finally, we get a ground truth of 773 migration rules with 190 different source libraries, distributed in 2,214 commit pairs from 1,228 repositories. This set of migration rules are mainly used for performance evaluations and comparison with other approaches, and denoted as $R_t$ in the remainder of this section.

In RQ1 and RQ2, we use the aforementioned 190 source libraries in $R_t$ as the query to our approach ($|Q| = 190$), which returns 243,152 candidate rules $^4$ ($|R_c| = 243,152$) along with the metrics, commits and confidence values. Note that the number of candidate rules is significantly larger than the size of ground truth rules ($|R_t| = 773$), which makes an effective ranking absolutely necessary. The recommendation only takes several minutes to finish with precomputed API Count data.

2) **GT2020**: We select the most popular 500 libraries based on the number of repositories they have been added. After filtering out existing source libraries in $R_t$, we get 480 libraries. We use them as query to our approach and collect their recommendation output, resulting in 383,218 candidate rules. To ensure that the migration rules we confirm are valuable for a broad audience and keep a reasonable amount of human inspection effort, we only inspect candidate rules that:

1) occur in top-20 recommendation result,
2) have been added in more than 10 repositories,
3) have non-zero confidence values.

After the filtering, we need to label 4,418 candidate rules in 12,565 pom.xml file changes, 2,353 commit pairs and 1,313 repositories. We repeat the labelling process as described before, and we successfully confirm 661 migration rules in 1,233 commits and 785 repositories, for 231 (48.125%) of the 480 libraries. In RQ2, we also use GT2020 to verify and compare the performance of our approach with existing approaches for the 231 libraries, despite its incompleteness.

By merging GT2014 and GT2020, we get 1,384 migration rules from 14,334 pom.xml changes, 3,340 commit pairs and 1,651 repositories (7.73% of the 21,358 repositories). If we

---

^4 The large number comes from Equation 7 which considers all possible migrations that spans over multiple revisions.
consider top 20% largest repositories in terms of commit numbers, 1,092 out of 4,271 repositories (25.57%) have undergone at least one library migration. Both percentages are higher than the reported percentage in [14] (5.57% and 9.95%), indicating that library migrations have become more prevalent in Java open source projects since 2014. The dataset is available on our project website (see Abstract).

C. RQ1: How effective is RS, MS, DS, and AS in identifying real migration targets from other libraries?

To answer RQ1, we plot survival functions for the confidence value of the approach in [12], the four proposed metrics, and the final confidence value of our approach, respectively.

For metric $M$, its survival function is defined as $y = P(M \geq x)$, where $P()$ is the probability function. We estimate the probabilities using GT2014, for both ground truth rules $R_t$ and other candidate rules $R_c - R_t$ in Figure 4. We can observe in Figure 4 that ground truth rules generally have significantly higher probability of survival for all metrics, indicating the effectiveness of each metric. We can also observe that any filtering threshold $x$ will result in either significant ground truth losses or undesirable survival of many other candidate rules due to their much larger quantity. Therefore, despite the effectiveness of each metric, we conclude that any filtering based method is inherently ineffective and we should leverage relative ranking positions instead of absolute metric values for selecting migration rules from the large number of candidates.

D. RQ2: What is the performance of our approach compared with baselines and existing approaches?

For performance evaluation, we use the following quality metrics common for evaluating ranking problems: Mean Reciprocal Rank (MRR) [26], top-$k$ precision, top-$k$ recall, and top-$k$ Normalized Discounted Cumulative Gain (NDCG) [27]. These metrics have also been used to evaluate other recommendation problems in software engineering [52]–[55].

Mean Reciprocal Rank (MRR) is defined as the mean of the multiplicative inverse of the rank of the first ground truth rule for all queries:

$$MRR = \frac{1}{|Q|} \sum_{q \in Q} \frac{1}{\min_{r \in \hat{R}_c \cap R} \text{rank}(q, r)}$$

(16)

It ranges between $[0, 1]$, and a higher value means that the user can see the first ground truth more quickly for each query.

Let $R_k$ be the top-$k$ ranked candidate rules for all queries, we define top-$k$ precision and top-$k$ recall as:

$$\text{Precision@}k = \frac{|R_k \cap R_t|}{|R_k|}$$

(17)

$$\text{Recall@}k = \frac{|R_k \cap R_t|}{|R_t|}$$

(18)

Normalized Discounted Cumulative Gain (NDCG) measures to what extent the ranking result deviates from the ideal result. For each library $l \in Q$ and its top-$k$ returned rules $R_{lk}$, let \( r(i) = 1 \) if the rank $i$ is in ground truth and 0 otherwise. By defining Discounted Cumulative Gain (DCG) as

$$DCG_l@k = \sum_{i=1}^{k} \frac{r(i)}{\log_2(1+i)}$$

and Ideal Discounted Cumulative Gain (IDCG) as $IDCG_l@k = \sum_{i=1}^{k} |R_{lk} \cap R_t| / \log_2(1+i)$, we further define NDCG@k as

$$NDCG_k = \frac{1}{|Q|} \sum_{q \in Q} \frac{DCG_l@k}{IDCG_l@k}$$

(19)

which ranges in $[0, 1]$ where 1 means a perfect match with ideal top-$k$ ranking result and 0 means the worst.

We first compare performance of our approach with the following alternatives using GT2014:

- **Teyton et al.** [12]: Use $\text{conf}_{TF}$ (Equation 6) for ranking.
- **Teyton et al.’** [12]: Keep rules $\text{conf}_{TF} \geq 0.002$ and rank.
- **Teyton et al.”** [12]: Keep rules $\text{conf}_{TF} \geq 0.015$ and rank.
- **Alrubaye et al.** [17]: Filter out RS $< 0.6$ or $AC = 0$.
- **RS Only**: Use only RS for ranking.
- **MS Only**: Use only MS for ranking.
- **MS**: Use RS · MS for ranking.
- **RS · MS · DS**: Use RS · MS · DS for ranking.
- **RS · MS · AS**: Use RS · MS · AS for ranking.

We choose three thresholds for Teyton et al. [12] to demonstrate its performance under different conditions, and tune parameters for Alrubaye et al. [17] to align with its reported performance. We only show MRR, top-1 precision, top-10 NDCG and top-20 recall due to space constraints, where MRR and top-1 precision measures accuracy, top-10 NDCG measures idealness, and top-20 recall measures completeness.

The performance comparison results are shown in Table III. Our approach can outperform all alternatives in term of top-20 recall, while keeping high top-1 precision, MRR and top-10 NDCG. Although aggressive filtering approaches like Teyton et al.’ and Alrubaye et al. have higher precision, NDCG, and MRR\(^5\), their recall is significantly lower than other approaches because of the filtering. The comparison with other metric combinations also shows that all four metrics are necessary to achieve the best performance. Therefore, we conclude that our approach achieves the best overall performance and is the most suitable one for migration recommendation, compared with the evaluated alternatives.

To demonstrate the generality of our approach, we further compute the quality metrics using GT2020 for the 231 queries. Since GT2020 is incomplete, we also show performance of Teyton et al.’ for comparison. Note that precision and MRR will be lower than their real values, and top-20 recall is 1 because we only check until top-20 results. However, we can

\(^5\)More results (including F-measures) are available on our project website.

\(^6\)Note that precision, NDCG and MRR basically measures the same thing if only one or very few items are returned for each query.
still observe that our approach outperforms Teyton et al.’ with a similar margin as in Table III. For example, the MRR of our approach is 13.1% higher than Teyton et al.’ in Table IV and 16.8% higher in Table III. Therefore, we conclude that our approach generalizes well in an unknown dataset.

VI. RECOMMENDATION EXAMPLE

Table V presents one recommendation example from our results: com.mchange:c3p0. It is a database connection pooling library which has been renamed to com.mchange.c3p0 since version 0.9.2 in 2007. Many other competitors for database pooling also emerged from 2007, under different licenses or for specific scenarios. We choose com.mchange:c3p0 as an example not only because of the diversity of migration targets returned, but also because it well demonstrates common failures and peculiarities of our approach. We can see from Table V that the top-1 recommended target is com.mchange.c3p0, with much higher confidence than the rest. The second result is Hikari CP, a database pooling library since 2013, which boasts its light-weight and much higher performance compared with other libraries. The 5th and 10th result is Alibaba Druid, a connection pool designed specifically for monitoring purposes. The 7th result is c3p0 for integrated use with Hibernate. The 15th result is Apache Commons DBCP, a pooling library under the ASF license. The rest of the results are omitted in the Table because they are all false positives. Given the prevalence of migrations from c3p0:c3p0, a developer should also consider abandoning it for his/her project, and choose one of the above libraries instead after evaluating the migration costs, benefits, licenses and other factors through investigation of the migration commits and other available information.

VII. LIMITATIONS

A. Failure Case Analysis

Cold Start. The most obvious failure case in our approach is that, it can only recommend migration targets that have been frequently migrated in the project corpus. However, this limitation can be mitigated by using a large project corpus, because the more worthy a migration is, the more common it will be in such a corpus. As shown in [15], 33 of 223 ASF projects have undergone at least one logging migration, mostly from ad-hoc logging libraries (e.g. log4j) to log abstraction libraries (e.g. slf4j) and log unification libraries (e.g. logback), and our approach performs well in these popular migrations. Developers can also conclude that a library is not a worthy migration target if it is absent in our result, even if it provides similar functionalities.

Data Sparsity. Other failure cases are generally caused by the sparsity of many real migrations in our data. If only one or several relevant commits can be identified for a query, other added libraries in these commits tend to occur as false positives together with the true migration target (e.g. hibernate-core in Table V). MS and AS can handle such cases, but they sometimes fail either because developers do not write informative commit messages, or because code changes are not needed for the migration or are completed before/after the pom.xml changes.

Miscellaneous. Our approach will fail if a library has no substitute at all, and it cannot issue any warnings in such cases. Our method of matching commit messages sometimes falsely identify a migration, and can be improved by more sophisticated NLP techniques. Our approach also frequently returns Bills of Materials, libraries that warp other libraries, or “full solution” frameworks like Spring in our results. Even if they are not considered as migration targets during the labelling process, they may still be useful for developers.

B. Threat to Validity

1) Construct Validity: The metrics are mainly designed to achieve high performance in the formulated problem, and may not be a good indicator on the appropriateness or optimality of a given migration for a specific project. Further research is needed to understand factors that drive library migrations, in order to design a better recommendation approach. Even in term of performance, we cannot guarantee that the metrics we design and the parameters we choose are optimal. To avoid over-fitting on a single dataset, we choose the simplest possible form for each metric, and evaluate our approach on an additional dataset. For evaluation, it is generally impossible to compute accurate recall for all possible migration targets in the wild [12], [14]. Even if we limit the evaluation on a set of ground truth libraries, we cannot guarantee completeness of the identified migration targets. To mitigate this threat, we aggressively extend the largest set of migration rules from existing work [14] and validate all extended rules, to present a “best effort” estimation of recall for GT2014 in RQ2.

2) External Validity: Our approach may not generalize to a different dataset (e.g. industry projects) and to other
programming languages and library ecosystems. We mitigate this threat by collecting a large number of open source Java projects and libraries, and testing on many library queries. Also, our approach in Section III does not make any language specific assumptions and can be easily re-implemented for other programming languages. Others can also refer to Section IV as an example of how to make implementation choices for a specific language or library ecosystem.

VIII. RELATED WORK

In this section, we go through related works not discussed before, and we summarize the relationship, differences or improvements of our work compared with theirs.

To recommend libraries to developers, Thung et al. [52] propose to recommend libraries based on the libraries a project is already using, through association rule mining and collaborative filtering. More approaches are proposed for this problem later, such as multi-objective optimization [55], hierarchical clustering [56], advanced collaborative filtering [57], matrix factorization [58], etc. However, their main objective is to recommend missing or redundant APIs based on the libraries a project is using and the properties of the project, not to recommend migration opportunities of a library already in use. Chen et al. [20] mine semantically similar libraries by training word embedding on Stack Overflow tags. Given a library, their method can return a list of possibly similar libraries, but it provides no evidence on the feasibility and prevalence of migrations between this library and the returned libraries.

Mora et al. [21] study the role of common metrics in developer selection of libraries. Alrubaye et al. [18] analyze several code quality metrics before and after library migration. They all use existing metrics for empirical analysis, while we specifically design new metrics for accurate mining and recommendation of migrations from existing software data.

A number of studies have proposed methods for mining API mappings of two similar libraries [13], [16], [19], [41], [44], [59] or directly editing code to use the new API [60], [61]. Zheng et al. [59] mine alternative APIs from developer shared knowledge in forums or blog posts. Gokhale et al. [41] build mappings by harvesting the execution traces of similar APIs. Teytton et al. [13] find API mappings by analyzing their co-occurring frequencies in existing migrations. Alrubaye et al. improve their method using information retrieval techniques [16] and machine learning models [19]. Chen et al. [44] propose an unsupervised deep learning based approach that embeds both API usage patterns and API descriptions. Xu et al. [60] propose an approach to infer and apply migration edit patterns from existing projects. Collie et al. [61] propose to model and synthesize library API behavior without prior knowledge, which can be used for identifying migration mappings and applying migration changes. The output of our approach can serve as input for any of the approaches above, because they all require manual specification of library pairs. Our new migration dataset may also be helpful in facilitating further research into this area.

Other recent works also aim to aid dependency management, but from a different perspective, such as characterizing library usage [6], versioning [62]–[64] and update behavior [38], discovering considerations for library selection [21], [24], resolving version conflicts in dependency tree [65], [66], in multi-module projects [67], and so on.

IX. CONCLUSION AND FUTURE WORK

In this paper, we propose an approach for automated recommendation of library migration targets, through mining dependency change sequences of a large corpus of software projects. We formulate this problem as a mining and ranking problem and design four advanced metrics for ranking. To the best of our knowledge, our approach achieves best performance in this problem domain. We also verify and build a latest migration dataset for further research. In the future, we plan to improve our approach to overcome current limitations (Section VII), collect usage feedback from industry developers, and extend the migration rule dataset in a crowd-sourced manner. We also plan to systematically investigate developer considerations for library migration, using the collected migration dataset.

ACKNOWLEDGMENT

This work is supported by the National Key R&D Program of China Grant 2018YFB1004201, the National Natural Science Foundation of China Grant 61825201, and the Open Fund of Science and Technology on Parallel and Distributed Processing Laboratory (PDL) No.6142110810403. We also want to thank Audris Mockus for providing tutoring and access to World of Code, and Xiao Cheng for his valuable comments.
